Coding in Python

Python Basics - Part 1

IDPO 2910 Group 5

20 April 2024

THE HONG KONG
UNIVERSITY OF SCIENCE
AND TECHNOLOGY

What is Python?

Did you know? Python was made by someone who was bored.
It's a language designed to be almost as understandable as English.
You will be using Python 3. Why? Because Python 1 are 2 are dead.

This is the logo of Python.

Loops
Input/Output
Variables

The first thing in Python - `print()` function

```
print("This is the print function.")
```

The first thing in Python - `print()` function

`print()` is a function that lets you print something, also known as text output.

```
print("Word") # This prints the word "Word".
```

Output:

```
>>> print("Word")
Word
>>> print("Haha hehe")
Haha hehe
```

input() function

We know how to output strings, what about input?

```
input("This is the input function.")
```

input() function

input() is a function that outputs a prompt and lets the user enter something.

```
>>> input("Enter a number: ")
Enter a number: 5
```

Simply inputting doesn't do anything, but we can print it.

```
>>> print(input("Enter a number: "))
Enter a number: 100
100
```

Variables

Variables

Imagine you borrow a box from the computer.

Give it a name and a value, you can now recall this value with the name!

Variables

The code usually goes:
`variable_name = data`
This means whatever `data` is, it is now stored in a variable with name `variable_name`.

Some basic variable types:

```
a = 5       # This is an integer (int) stored in a
b = True    # This is a boolean (bool) stored in b
c = 3.2     # This is a float (float)  stored in c
d = "abc"   # This is a string (str)   stored in d
e = 'abc'   # This is also a string    stored in e
```

Variables - Integers

What are integers?
Integers are just like what you've learnt in Maths, numbers without decimal points.

```
a = 5         # Valid
b = 12        # Valid
c = 69420     # Valid
d = -1984     # Valid
e = 32.5      # This would become a float instead
f = '5'       # This would become a string instead
```

Variables - Integer Arithmetic Operations

You can do normal operations on integers:

```
a = 1 + 2   # a stores the integer 3
b = 80 - 52 # b stores the integer 28
c = 69 * -2 # c stores the integer -138
d = 6 / 4   # d stores the float 1.5
e = 18 / 2  # e stores the float 9.0
```

Division in Python

Whether a number can be precisely divided or not, division returns a `float`.

Variables - Integer Arithmetic Operations

Operations with variables:

```
a = 100
b = 12
c = a + b    # c stores the integer 112
d = b - a    # d stores the integer -88
e = a * -b   # e stores the integer -1200
f = a / b    # f stores the float 8.333333333333334
```

Variables - Integer Arithmetic Operations

Then how do we get an integer output?

```
a = 100
b = 12
c = a // b  # c stores the integer 8
            # // operator takes the closest and smaller
            # integer from the division operation
d = a % b   # d stores the integer 4
            # % operator takes the remainder of a
            # division operation
```

Variables - Integer Arithmetic Operations

Also, the power (exponent) operation:

```
a = 2
b = 5
c = a ** b  # c stores the integer 32
            # ** operator means power
```

Variables - Floats

What are floats?
Floats are numbers with decimal point(s).
Arithmetic operators we learnt can be applied as well.

```
a = 0.2      # a stores the float 0.2
b = 3.0      # b stores the float 3.0
c = a + b    # c stores the float 3.2
d = b / a    # d stores the float 15.0
e = a ** b   # e stores the float 0.008000000000000002
```

Inaccuracies

Inaccuracies happen with decimals in Python. Be careful when dealing with floats.

Variables - Floats

What are floats?
Floats are numbers with decimal point(s).
We learnt about arithmetic operators: +, -, *, /, //, %, **
All of them, except // and % can be applied to floats.

```
a = 0.2      # a stores the float 0.2
b = 3        # b stores the integer 3
c = a + b    # c stores the float 3.2
d = b / a    # d stores the float 15.0
e = a ** b   # e stores the float 0.008000000000000002
```

Arithmetic operations between `int` and `float`

Arithmetic operations between integers and floats converts the integer into a float first before operating.

Variables - Boolean values

What are boolean values?
There are only 2 boolean values in existence: `True` and `False`.

```
a = True
b = False
```

That's it.

Variables - Strings

What are strings?

```
a = "word"  # a stores the string "word"
b = 'word2' # b stores the string "word2"
c = '5.20'  # c stores the string "5.20"
d = 'abc"   # error
```

Quotes

In Python you must use corresponding quotation marks for strings.

Variables - Strings

How do I put the symbols ' and " into a string?
For ":

```
a = "word\"" # a stores the string "word""
b = 'word"'  # b stores the same string as a
```

Same goes for single quotes ':

```
a = 'word\'' # a stores the string "word'"
b = "word'"  # b stores the same string as a
```

Variables - Strings

There are additional symbols in strings.

```
a = "word\n" # \n represents the newline character
b = "word\t" # \t represents the tab character
```

Variables - Strings

```
a = "haha"
b = "hehe"
c = a + b     # c stores the string "hahahehe"
```

Concatenation of strings

You can concatenate (add) strings together with the addition symbol.

Type conversion

You can convert between types with their type names in Python.

Data Type	Command
Integer	`int()`
Float	`float()`
String	`str()`
Boolean	`bool()`

Focus

We will focus on `int()` today as it will be needed in your game.

Conversion with int()

int() tries to convert a variable into an integer.

```
a = 10          # int
print(int(a)) # 10
                # Nothing occurs

b = 3.7         # float
print(int(b)) # 3
                # Discards values to the right of
                # the decimal point

c = True        # boolean
print(int(c)) # 1

d = False       # boolean
print(int(d)) # 0
                # For boolean: 0 if False, True otherwise
```

Conversion with int()

```
i = "123abc"  # string
print(int(i)) # Error

j = "123"     # string with ONLY numbers
print(int(j)) # 123
              # Only integers in strings would be
              # successfully converted

k = "123.123" # string with ONLY numbers, but with
              # a number that represents a float
print(int(k)) # Error
```

Variables

Variables in output - Revisiting the `print()` function

How do we print variables?

```
a = 5
print(a)          # 5
b = "haha"
print(b)          # haha
print(a + 2)      # 7
print(b + "a")    # hahaa
print(a, b)       # 5 haha
print(b, b)       # haha haha
```

The comma

Using `,` in `print()` would add a space in between the 2 items.

Variables in output - Revisiting the `print()` function

How do we print variables?

```
a = 5
print(a)          # 5
b = "haha"
print(b)          # haha
print(a + "5") # error
print(b + 2)    # error
print(a + b)    # error
```

Addition

You cannot use addition to print things of incompatible types.

Variables in output - Revisiting the `print()` function

How do we print variables?

```
a = 5
b = 32
c = 32.0
print(a * b)     # 160
print(a * c)     # 160.0
```

Takeaway

`print()` function evaluates the expression inside the brackets first before actually printing.

More on `print()` function

In Python, the `print()` function automatically adds a new line after execution. We, however, can stop that.
The `end=` tag allows us to define the character added when `print()` is executed.

```
print(5, end="")
print(4)
print("a", end="abc")
print("d", end=" ")
print("e")
# What is the output?
# Output: 54
#         aabcd e
```

End of line

Remember to include a new line `\n` in the last line of a printed string. Else it may mess up the future outputs from other lines of the code or the computer terminal.

More on `print()` function

We mentioned that whenever `,` is used in `print()`, the items would be separated by a space.
This can actually be changed using the `sep=` tag.

```
>>> print("100", 100, end="\n3\n")
>>> 100 100
    3
>>> print("100", 100, sep="a", end="\n3\n")
>>> 100a100
    3
```

More on `print()` function

Another example:

```
>>> a = 5
>>> b = 10
>>> print(a, b, a + b, end="20\n")
>>> 5 10 1520
>>> print(a, b, a + b, sep="", end="20\n")
>>> 5101520
>>> print(a, b, a + b, end="20\n", sep="")
>>> 5101520
```

Command Parameters

As long as you mark `sep` and `end` clearly **and** after the things you want to print, the ordering doesn't matter!

Converting the type of an input

How do we convert the data type of variables?

```
>>> number = input("Enter your number: ")
Enter your number: 50
>>> print(number)
50
>>> print(number + 1000) # Error occurs. Why?
```

Explanation

number is a string type while 1000 is an integer.

Converting the type of an input

How do we convert the data type of variables?

```
>>> number = input("Enter your number: ")
Enter your number: 50
>>> print(number)
50
>>> print(int(number) + 1000) # 1050
```

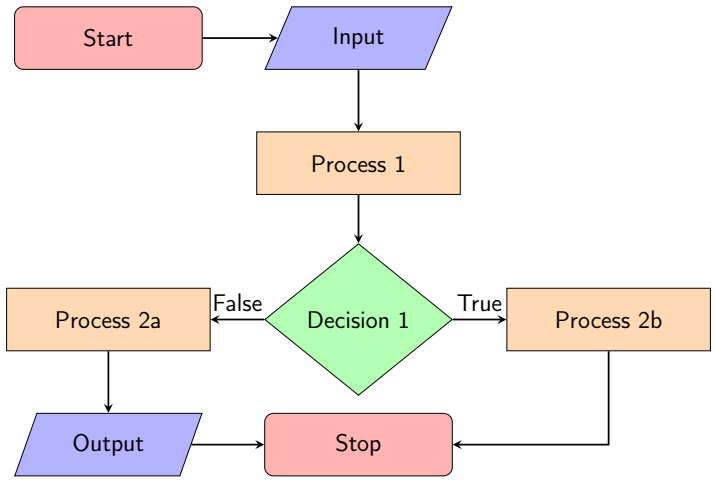
Program (Codes)
Functions
Decision Making
Loops
Input/Output
Variables

Decision Making

What is decision making?

We use condition(s) to decide whether some code should be run.



The if clause

```
a = 5 # a stores the integer 5
if a == 5:
    print("a stores 5.") # This line is activated

b = 10 # b stores the integer 10
if b == 5:
    print("b stores 5.") # This line is not activated
```

The if clause

If the condition is true, then the code under it is run.

The == operator

```
a = 5 # a stores the integer 5
if a == 5:
    print("a stores 5.") # This line is activated

b = 10 # b stores the integer 10
if b == 5:
    print("b stores 5.") # This line is not activated
```

The == operator

The operator == is used to compare 2 values. If the values on the both sides are the same, then it becomes `True`. It becomes `False` otherwise.

The if-else clause

```
a = 5 # a stores the integer 5
if a == 5:
    print("a stores 5.") # This line is activated
else:
    print("a does not store 5.")

b = 10 # b stores the integer 10
if b == 5:
    print("b stores 5.")
else:
    print("b does not store 5.") # This line is activated
```

The else statement

Code under the else statement is executed when the condition in if is not true.

The if-else clause

```
a = 5 # a stores the integer 5
if a == 5:
␣␣␣␣print("a stores 5.") # This line is activated
else:
␣␣␣␣print("a does not store 5.")

b = 10 # b stores the integer 10
if b == 5
␣␣␣␣print("b stores 5.")
else:
␣␣␣␣print("b does not store 5.") # This line is activated
```

Indentation in Python

Indentation decides whether the code is under the if/else statements.
It does not have to be 4 spaces, but they have to be **consistent**.

The if-elif-else clause

```
a = 5 # a stores the integer 5
if a == 5:
    print("a stores 5.") # This line is activated
elif a == 10:
    print("a stores 10.")
else:
    print("a does not store 5 or 10.")
```

The elif statement

The elif (stands for else-if) statement is a secondary if statement that is run if the previous if/elif condition(s) are not true.

The if-elif-else clause

```
a = 15 # a stores the integer 15
if a == 5:
    print("a stores 5.")
elif a == 10:
    print("a stores 10.")
elif a == 15:
    print("a stores 15") # This line is activated
else:
    print("a does not store 5, 10 or 15.")
```

Stacking the elif statement

The elif statement can be stacked on top of one another.

Comparison Operators

We've learnt that == means "equal to". What are some other operators?

Operator	Meaning
==	equal to
>	larger than
>=	larger than or equal to
<	smaller than
<=	smaller than or equal to
!=	not equal to

Decision Making and Comparison Operators

```
a = 10 # a stores the integer 10
if a > 5:
    print("a is larger than 5")

if a >= 10:
    print("a is larger than or equal to 10")
```

In this example, both `print()` statements are activated.

Decision Making and Comparison Operators

```
a = 10 # a stores the integer 10
if a > 5:
    print("a is larger than 5")
elif a >= 10:
    print("a is larger than or equal to 10") # Not run
```

In this example, only the first `print()` statements are activated.

`if` vs `elif`

If a condition is fulfilled, any `elif` clauses afterwards will not be considered.

Logic Operators - and

The and operator denotes whether the 2 conditions are fulfilled **at the same time**.

Example:

```
a = 10 # a stores the integer 10
if a > 5 and a < 9:
    print("a is between 5 and 9")
else:
    print("a is not between 5 and 9") # This line is run
```

Logic Operators - or

The `or` operator denotes whether **any** of the 2 conditions are fulfilled.

Example:

```
a = 10 # a stores the integer 10
if a < 5 or a > 9:
    print("a is not between 5 and 9") # This line is run
else:
    print("a is between 5 and 9")
```

Logic Operators - not

The not operator reverses the condition.

Example:

```
a = 10 # a stores the integer 10
if not a == 5: # Same as a != 5
    print("a is not 5") # This line is run
else:
    print("a is 5")
```

Multiple Logic Operators

```
a = 10 # a stores the integer 10
if not a % 2 != 0 or a == 1: # Same as a % 2 == 0 or a == 1
    print("a is even or equal to 1")
else:
    print("a is odd and not equal to 1")

b = 10 # b stores the integer 10
if b == 5 and not b % 2 != 0: # Impossible condition
    print("b is 5 and somehow even?")
else:
    print("else statement")
```

Multiple Logic Operator (out of control)

We can use multiple logic operators together, but what about the rules?

```
a = 10 # a stores the integer 10
if not a == 0 and a == 1 or a == 3 and a % 2 == 1:
    print("What is going on in the conditions?")
else:
    print("Else statement")
```

Multiple Logic Operator (out of control)

We add brackets () to make our conditions clear.

```
a = 10 # a stores the integer 10
if (not a == 0 and a == 1) or (a == 3 and a % 2 == 1):
    print("Now the conditions are clearer")
else:
    print("Else statement")
```

Reminder

If you ever use > 1 and/or operators, add brackets to keep track of what your conditions are.

Generating a random integer using `random` library

In Python, we can import libraries to help us with tasks. One of them is generating random numbers. The library/package `random` allows us to get a random number.
The `randint` function provided allows us to generate a random integer given a range.

```
import random
num = random.randint(1, 10) # generates a random number
                            # We passed 1 and 10 into randint,
                            # so the number can only be
                            # from 1 to 10
print(num) # prints the number
```

Generating a random integer using `random` library

Another example:

```
import random
min = 15
max = 30
print(random.randint(min, max)) # prints a random number
                                # from 15 to 30
```

Generating a random integer using `random` library

Another example with decision making:

```
import random
num = random.randint(1, 10)
if num < 5:
    print("The number is smaller than 5")
else:
    print("The number is larger than or equal to 5")
```

Summary

Variable types

There are 4 basic variable types: `int`, `bool`, `float` and `str`.

Arithmetic Operators

Some basic and commonly-used operators:

+:	add	-:	minus,
*:	multiply	/:	divide,
//:	quotient	%:	remainder,
**:	power		

Type Conversion

To convert between types, you can simply surround the target with brackets, and call the type.

`int -> int()`; `bool -> bool()`; `float -> float()`; `str -> str()`.

Summary

The `print()` statement

```
print(*objects, sep=' ', end='\n', file=None, flush=False)
```

`*objects` - the things you want to print,
`sep` - the string that separates `objects` (when using commas),
`end` - the string to end the print statement with.
The other arguments can be ignored as they are rarely used.

The `input()` statement

```
input(prompt)
```

where `prompt` is quite literally what it means. It prints the output, then returns the value inputted as a string.

Summary

if, elif and else

if, elif and else clauses are used to decide whether some code should be executed. Whenever one is fulfilled, all others are ignored.

```
if condition1: # if condition1 is true
    # Do something, ignore all elif and else below

elif condition2: # if condition2 is true
    # Do something, ignore all elif and else below

elif condition3: # if condition3 is true
    # Do something, ignore all elif and else below

else: # if all the conditions above are false
    # Do something
```

Summary

The `and` logic operator

The `and` operator makes it so that both conditions have to be fulfilled in order for the code it is under to execute.

The `or` logic operator

The `or` operator makes it so that only 1 of the conditions have to be fulfilled in order for the code it is under to execute.

The `not` logic operator

The `not` operator reverses the condition is it attached to.

Multiple logic operators

One can chain multiple logic operators together, but to be safe add brackets () to make sure the condition works as intended.

Summary

`random.randint()`

`random.randint(a, b)`

`a` - the lower bound of your range

`b` - the upper bound of your range

This generates an integer `n` where $a \leq n \leq b$.

The end
